For more than half a century threshold phenomena in nuclear reactions have been drawing attention of researchers by its unique capability for a detailed study of nuclei structure near the energy threshold of opening of any reaction channel, since here occurs an abrupt change of energy dependence of physical quantities characterizing a compound system, caused by its radical internal reconstruction. A flow of probability conservation causes a unitarity of collision matrix, what together with a requirement for reaction amplitude analyticity, conditioned by a causality principle, is a basis for the formal apparatus of threshold phenomena theory (TPT). Specific features of behavior of differential and total cross-sections of reaction channels and elastic scattering near a threshold of one of the channels were predicted by E.Wigner in the year 1948 [1]. In a decade (in the year 1957) G. Breit [2] and A. Baz [3] there was built a consistent TPT theory, which was generalized on the basis of Feshbach microscopic theory [4] by L.M. Lasarev [5] in case of multi-particle reactions and resonances in the compound nucleus near the threshold.

The report represents a review of experimental data on threshold anomalies in a few nucleon systems. As an illustration of wealth of spectroscopy information, obtained when studying threshold anomalies, the system  ${}^7\text{Li}+t$  near the threshold  ${}^7\text{Li}(t,n){}^9\text{Be}^*(E_x=14.4\text{ MeV}, T=3/2)$  is considered. Analysis of excitation functions of  ${}^7\text{Li}+t$  reaction channels has allowed obtaining of energy of the lowest levels with isospin  $T=2$  of nuclei  ${}^{10}\text{Be}$ , determination of their spins and parities, as well as quantum characteristics of nucleon-unstable nucleus  ${}^{10}\text{Li}$ , its mass and energy of the first excited level [6].
